Abstract

Poor compliance with Levothyroxine therapy leading to apparently 'resistant' hypothyroidism, termed 'pseudomalabsorption', is a common clinical conundrum. A thyroxine absorption test may aid clinicians in confirming suspected poor compliance with greater objectivity, but there is a lack of uniformity in practice and interpretation of this test. We herein report a case of suspected pseudomalabsorption where a thyroxine absorption test helped to confirm the diagnosis. A 29-year-old female was diagnosed with primary hypothyroidism in 2009 with TSH at diagnosis of 180 microIU/L. Euthyroidism was achieved by Levothyroxine administration, which was gradually increased to 175mcg/day. In the subsequent 2 years, however, she remained persistently hypothyroid despite doses of Levothyroxine well exceeding her estimated weight adjusted requirement. A thyroxine absorption test was performed, where once weekly directly observed administration of a weight-adjusted dosage of levothyroxine was performed over a consecutive 4 week period. TSH fell from a baseline of 18 microIU/L to 0.8 microIU/L in the fifth week. This finding confirmed pseudomalabsorption and excluded the need for a potentially exhaustive search for an organic underlying cause for the persistently elevated TSH.

Keywords: Hypothyroidism; Non-compliance; Malabsorption

Introduction

Primary hypothyroidism is the most common cause of hypothyroidism, and typically responds well to oral Levothyroxine replacement therapy. Factors interfering with Levothyroxine absorption such as co-ingestion of foodstuffs and/or medications, or underlying gastroenterological conditions such as celiac disease, can result in apparent resistance to Levothyroxine therapy - with difficulty achieving a normal TSH and a requirement for high doses of levothyroxine. Poor compliance with Levothyroxine, if denied by the patient, can present with a similar clinical picture hence the term 'pseudomalabsorption' has been applied in such cases. In the scenario where pseudomalabsorption is suspected, but is

refuted by the patient, a breakdown in the therapeutic relationship between the patient and the treating physician can easily develop. By providing objective evidence of the presence or absence of levothyroxine malabsorption under controlled conditions the Thyroxine absorption test may aid clinicians in establishing poor compliance with relative objectivity and confidence, and can potentially restore the therapeutic relationship. Confirming a diagnosis of pseudomalabsorption using the Thyroxine absorption test may also negate the need for an exhaustive search for other causes of malabsorption or resistant hypothyroidism, and can also justify lowering of the often excessively high thyroxine dosage.

Figure 1: TSH (microIU/L) and free T4 (pmol/L) measurements over the period July 2014 to October 2016.

Case Report

A 29 year old female was diagnosed with primary hypothyroidism in 2009, when she presented with symptoms of hypothyroidism, easy fatigability, excessive sleep, hair and skin dryness, and weight gain. Her TSH at diagnosis was 180 microIU/L (0.5-5 microIU/L), free T4 was 4.5 pmol/L (9-22pmol/L) and TPO Antibodies strongly positive. She was initiated on Levothyroxine 75mcg/day and subsequently achieved euthyroidism when

Table 1: TSH and levothyroxine dose requirements over the last three visits before starting thyroxine absorption test.

Visit date	TSH (microIU/L)	Free T4 (pmol/L)	Body weight In kilogram	Weight adjusted Levothyroxine dose (mcg/kg)
Apr-16	18	8.2	80	2.81
Jul-16	6	17	79	3.32
Oct-16	34	6.6	81	3.43

This biochemical picture was in accordance with her complaints of persistent hypothyroid symptoms, reduced daily activity due to easy tiredness, and difficult to lose weight (Table1). She did not manifest any signs and symptoms of malabsorption. She reported taking her tablets in the early morning on an empty stomach. She was not any other medications, making medication interference with Levothyroxine absorption unlikely. Laboratory parameters as a rudimentary screen for malabsorption were essentially normal: her hemoglobin was 12.6 g/dL (12.3-15.3 g/dL), albumin 43 g/l (35-55 g/l), 25-hydroxy vitamin D 59 ng/mL (20-100 ng/mL), and calcium 2.4 mmol/L (2.10-2.60 mmol/L), and anti transglutaminase antibodies were not detected. With careful explanation and with consent from the patient, a thyroxine absorption test was conducted. The patient attended the Endocrinology outpatient on consecutive Mondays for 4 weeks to have a directly-observed intake of her estimated weight-adjusted replacement weekly dose of Levothyroxine (applying the formula of [weight(kg) x 1.6 mcg/kg/day x 7 day], with her weight measured at 80kg, the weekly weight-adjusted Levothyroxine dose requirement was estimated to be 900mcg).

Thyroid function testing was performed at baseline prior to the first observed dose and on the Monday of the fifth week, a week after the last observed dose. Baseline TSH was 18 microIU/L, and free T4 was 6.6 pmol/L (9-22 pmol/L). On the fifth week of the test, TSH had normalized with a reading of 0.8 microIU/L and free T4 was also normal at 15 pmol/L. With this objective result, we concluded with confidence that the persistent hypothyroidism in this patient was related to poor compliance with Levothyroxine therapy. This was explained to the patient who was relieved to find that there were no treatable organic causes for such derangement, and that a further search for a cause was not needed. A lower Levothyroxine dose was also justified in light of this test result, and the patient was prescribed 125mcg/day of Levothyroxine, an approximately 50% reduction in her prior prescribed dose. Her repeat TSH after 6 weeks on this lower dose remained in the normal range at 1.2 microIU/L.

Discussion

Primary hypothyroidism accounts for more than 90% of cases of hypothyroidism and oral Levothyroxine replacement of

Levothyroxine was titrated to 175mcg/day. In 2011 she delivered a healthy boy uneventfully with TSH within target limits while on similar dosages. Between January 2014 and October 2016, however, her TSH remained persistently elevated, despite increasing Levothyroxine dosage (Figure 1). She was subsequently referred to Endocrinology clinic. At her first clinic visit we noted that the patient remained persistently hypothyroid despite being on Levothyroxine doses of 250-275mcg/day (Table 1).

1.6-1.8mcg/kg/day restores a euthyroid state in the majority of patients if taken function tests appropriately and absorbed into the bloodstream. As shown in Table 2, however, many conditions or coexisting medications can lead to interference with absorption of Levothyroxine or a requirement for higher doses than are typically required. A persistent hypothyroidism even with levothyroxine dosage exceeding the usual weight-adjusted required dose may prompt further assessment of levothyroxine malabsorption and poor compliance, the later being a diagnosis of exclusion which is difficult to confirm as it is based on a patient's voluntary self-report. Generally, the adherence rate to therapy in patient with hypothyroidism is around 65% [1] (Table 2). A Thyroxine absorption test is a useful tool to rule out malabsorption as a cause for a high Levothyroxine dose requirement or apparent 'resistance' to Levothyroxine in a single test with objectivity and confidence. An improvement in thyroid post-test essentially rules out thyroxine malabsorption and renders further investigations unnecessary.

Table 2: Causes of increase levothyroxine requirements in hypothyroid patients.

Causes of Increase Levothyroxine Requirements in Hypothyroid Patients	
physiologic requirement for higher doses	
-	Pregnancy
-	Estrogen therapy
-	Weight gain
Drugs which increase catabolism of T4	
-	Rifampin
-	Carbamazepine
-	Phenytoin
-	Phenobarbital
-	Tyrosine kinase inhibitors
Malabsorption or increased excretion of T4	
-	Gastrointestinal disorders (eg, celiac disease)
-	Impaired acid secretion
Drugs that interfere with T4 absorption if co-ingested	
-	Ferrous sulfate

- Cholestyramine or colestipol
- Sucralfate
- Aluminum hydroxide gels
- Calcium carbonate
- Sertraline
- Raloxifene
- Proton pump inhibitors
Nephrotic syndrome
Previous thyroid irradiation
Food
- Dietary fibre
- Dairy products
- Coffee
- Milk

Table 3: Common used protocols of thyroxine absorption tests.

Type	Duration	Protocol
Short/rapid absorption test [4-6]	6 hours	After an overnight fasting
		Administer 1000 µg of LT4
		Inspect of the oral cavity and observe behavior for 60 minutes post ingestion
		Measure TSH at 0, 1 and 2 hours
		Measure free T4 at 0, 30, 45, 60, and 120 minutes (up to 240 minutes in some protocols)
Long absorption test [7]	5 weeks	After an overnight fasting
		Administer a dose of 1.6 µg /kg/day on weekly basis for 4 weeks
		Observe the patient for 1 hour after each ingestion
		Measure TSH and free T4 at 0, 1, 2, 3 and 4 hours after ingestion
		Measure TSH and free T4 after 1 week of the final dose
Modified absorption test [2,3]	5 days	After overnight fasting each day
		Administer the patient own dose in the morning for 5 consecutive days
		Observe the patient for 1 hour after each ingestion
		Measure TSH, free T4 and FT3 at day 1 and day 5

As compared to a long thyroxine absorption test, the shortcomings of performing a short thyroxine absorption test are that the results can be more difficult to interpret and the applied single dose is generally much higher (usually exceeding 1000 mcg) and may not be well tolerated, particularly in patients with a lower weight. The absence of standardized methodology and specific cut-offs for a positive test has resulted in difficulty implementing this test in clinical practice. The complexity of its interpretation can be demonstrated by the formula proposed to calculate the percentage of absorbed thyroxine to rule out malabsorption depending on volume of distribution [9] (Table 4). One study of 23 patients with persistently elevated TSH, which compared the long and short thyroxine absorption tests, showed that 6/23 patients had persistently increasing TSH after 4 weeks from baseline despite an initial rise in free T4 (median >50%) post 120 minutes ingestion and despite appropriate levothyroxine replacement using weight-determined oral levothyroxine [7].

A normal test also justifies lowering the Levothyroxine dosage to predicted weight-adjusted requirement. With the lack of a standard protocol for the tests, many variations of the test exist, albeit all are based on the same underlying principle. Three main variations of the thyroxine absorption test exist, namely: the short thyroxine absorption test; the long absorption test; and the modified absorption test. These tests require 6 hours, 5 weeks and 5 days to complete respectively (Table 3). All versions of the test report good utility in distinguishing between malabsorption versus noncompliance [2,3] (Table3). The long thyroxine absorption test was adopted in our scenario; the weekly dose administered in this test is well tolerated generally and in the absence of malabsorption the TSH is expected to fall (and normalize), although to a lesser extent compared to the daily dose [4-7]. In a trial of 12 hypothyroid patients, 7 who were assigned to daily Levothyroxine doses and 5 assigned to weekly doses, the mean serum TSH was 3.92 microIU/mL and 6.61 microIU/mL respectively [8].

Conclusion

In patients with suspected ‘pseudomalabsorption’ of Levothyroxine the Thyroxine absorption test may aid clinicians in establishing poor compliance with objectivity and confidence. The lack of uniformity in practice or interpretation of this test may have led to it being underutilized heretofore. We report a case of pseudomalabsorption where a long thyroxine absorption test allowed us to objectively prove adequate Levothyroxine absorption, leading to reduction in Levothyroxine dosing, and restoration of euthyroidism without the need for potentially more invasive testing and without a breakdown in the therapeutic relationship with the patient. A better understanding of these tests and adoption of standard protocols is crucial for future research.
