Introduction

The terahertz (THz) region of the electromagnetic spectrum is distributed from 0.1 to 10 THz. It has high transmittance in non-metallic materials, and the frequency of THz radiation corresponds to the energy of weak intermolecular bonding and to transitions between rotational energy levels. Because of these characteristics, it is expected that THz radiation can be applied to specialized spectroscopic imaging [1], high speed telecommunications [2] and non-destructive inspection and measurement [3-5]. To the best of our knowledge, THz radiation presents no serious danger for the human body. Furthermore, there are many interesting applications for THz spectroscopy, for example, unambiguous monitoring of toxic materials without ionization, the detection and analysis of smoke in the atmosphere, and detecting small amounts of hazardous impurities [6-10]. The spectral lines for the rotational transitions of gas molecules are sharp and dense, so high resolution spectroscopy is necessary. Many THz radiation sources have been developed based on nonlinear optical (NLO) processes such as difference frequency generation (DFG) [11-12]. Furthermore, quantum cascade lasers (QCL) have been realized [13-15].

The advantages of DFG are that it operates at room-temperature, the radiation is monochromatic and the frequency is tunable over a wide range. In particular, the THz radiation from GaP pumped by a CW (continuous-wave) laser diode (LD) has very narrow linewidths that enable high-resolution THz spectra to be done [16,17]. To develop practical applications that use THz spectroscopy under normal atmospheric conditions, clear THz spectra of the omnipresent water vapor should be obtained. The absorption lines of water vapor are known to broaden with increasing pressure, so many of the previous theoretical and experimental studies reporting on the THz spectra of water vapor were done under ideal conditions, that is, at low pressure [7,18-22]. In this study, we used the system mentioned above, GaP pumped by a CW LD, as a THz source to make spectral measurements on a mixture of saturated
water vapor and ethanol at room temperature. We also measured the THz spectra of water vapor at different humidity levels at atmospheric pressure and in a vapor-liquid coexistence at reduced pressure.

Experimental

Figure 1 shows the optical setup for the THz spectral measurement system. The pump and signal lasers are an ECLD (external cavity laser diode) and a DFB (distribution feedback) laser, respectively. The wavelength range of the DFB laser was automatically tuned from 1058 to 1061 nm (0.6 THz) with a linewidth of 3 MHz by changing the temperature of the laser. The wavelength of the ECLD was manually tuned from 1020 to 1080 nm with a linewidth of 4 MHz. Two polarization maintaining ytterbium doped fiber amplifiers (FAs) were used and each laser diode was amplified up to 2 W. The THz frequency was changed continuously by tuning the wavelength of the DFB laser by temperature control. The details are described in our previous paper [12,17]. The GaP crystal was cut into a rectangle measuring 10 mm in the <110> direction and 3 mm in the <001> direction. A polarizing beam splitter was used to combine the pump beam with the signal beam. The incident beam angle was aligned roughly parallel to the <110> direction and the two lasers were focused onto the GaP surface at a phase matching angle. The CW THz radiation generated was reflected by parabolic mirrors, and the THz signal was detected using a liquid-helium cooled Si bolometer.

A gas cell with 4 mm thick polyethylene windows containing the ethanol/water vapor mixture was placed between the two parabolic mirrors in order to measure the spectra. The optical path length and volume of the cell were 232 mm and 0.12 L, respectively. THz spectra of the water vapor were taken at different humidity levels at atmospheric pressure, with an optical path length of 530 mm. The humidity was controlled by changing the flow rate of dry air. The absolute humidity of dry air with a dew point of ≤ -70 °C is 4.74 × 10^-3 g/m^3, which is 0.019 % relative humidity at 20 °C. The humidity was measured using a thin film capacitive relative humidity sensor. The pressure in the gas cell was reduced by using a diaphragm pump, and the pressure was measured by a bourdon tube pressure gage. Before evacuation, liquid water was introduced into the cell. Spectra of the water vapor were measured before and after evacuation, where the pressure in the gas cell under vapor-liquid equilibrium conditions at room temperature was 14.6 kPa.

Results and Discussion

Figure 2(a) shows the THz spectrum of saturated water vapor and ethanol at atmospheric pressure and room temperature in the frequency range from 2.4 to 2.68 THz in 336 MHz steps. Several absorption lines are observed in this frequency region. The peaks shown by closed circles (●) are due to the rotational energy state transitions of water. The peaks shown by solid triangles (▲) are attributed to the rotational energy state transition lines of ethanol gas. The absorption spectrum around 2.46 THz was measured with a fine frequency step of 87 MHz, as shown in Figure 2(b). The absorption bands were separated with a Lorentz function, revealing peaks at 2.4658 THz and 2.4682 THz. This result suggests that the spectral resolution is within 2.4 GHz. Figure 3 shows the THz spectra of water vapor with different humidities at atmospheric pressure. The spectra were measured in the frequency range from 2.41 to 2.53 THz as a function of humidity at room temperature. As shown in Figures 3a & 3b, at humidities of 3.69 and 1.55 g/m^3, absorption peaks appear at around 2.40 THz, 2.44 THz, 2.45 THz and 2.47 THz. These absorption bands are assigned to the following rotational transitions of water: (4_{04} ← 3_{13}), (9_{36} ← 9_{27}), (8_{44} ← 8_{35}) and (4_{32} ← 3_{23}), respectively [23].

These absorption peaks are hardly observed at humidities less than 0.16 g/m^3. The position of the 2.47 THz absorption peak shifts to lower values and the FWHM becomes smaller as the number of surrounding water molecules decreases, and the nitrogen and oxygen start to have an effect on the interactions between the water molecules. Figure 3(e) shows the dependences of the peak position, the FWHM and the intensity of the absorption band on humidity. The absorbance and peak frequency are proportional to

the humidity of water vapor below 0.5 g/m$^3$. This indicates that the THz absorption is based on the Beer-Lambert law. For humidities above 1.5 g/m$^3$, the THz absorption is saturated due to interactions between the water molecules, and the FWHM is broadened by this increase in molecular interactions. The interaction is due to the polarity of the water molecules, and this is larger than that of alcohol. The interactions for alcohol molecules, which have more carbon atoms with a small proportion of -OH, is weaker. Figure 4 shows the THz spectra of water in a vapor-liquid coexistence at a pressure of 14.6 kPa.

The THz spectrum at atmospheric pressure is shown in Figure 4(a). An absorption peak, with a full width at half maximum (FWHM) of 5.92 GHz, is located at 2.569 THz. This is assigned to the rotational transition of water (7$^{34} \rightarrow 6_{43}$) [23]. The pressure in the gas cell was reduced by a diaphragm pump and the spectrum was measured soon after evacuation. The result is shown in Figure 4(b). A second, unknown absorption peak appeared at 2.585 THz. The cell was then left untouched and the spectra were measured after 30 and 60 minutes. As shown in Figures 4c & 4d, the absorption peak at 2.585 THz has disappeared, while at the same time, the intensity of the peak at 2.569 THz has increased. The peak at 2.585 THz is thought to be from clusters of water molecules, since the reduced pressure makes the temperature lower for water molecules, so the hydrogen bonds of some water molecules become tighter, forming clusters and giving rise to the absorption peak at the higher frequency. It has been reported that there is a water trimer with an absorption line at 2.61 THz due to $k = 3 \ell = 0$ of (H$_2$O)$_3$ [24]. For stable water clusters, the (H$_2$O)$_2$H$^+$ cluster has many absorption lines in the frequency range from 1.5 to 6 THz [25]. More experiments are needed in order to further this discussion.

**Figure 2:** THz spectra of a mixture of saturated water vapor and ethanol at atmospheric pressure with frequency steps of 3.36×10$^{-4}$ THz (a) and 8.7×10$^{-5}$ THz (b), respectively.

**Figure 3:** THz spectra of water vapor at different humidity levels at atmospheric pressure. The humidity is 3.69 g/m$^3$ (a), 1.55 g/m$^3$ (b), 0.480 g/m$^3$ (c) and 0.160 g/m$^3$ (d), respectively. (e) Dependences on humidity of the absorption peak position, the FWHM, and the intensity of the absorption band around 2.47 THz due to the rotational transition of 4$^{32} \rightarrow 4_{23}$.
Conclusion

A LD pumped CW THz radiation generator was combined with a gas cell to obtain high resolution THz spectra of water vapor. In the spectra of a mixture of saturated water vapor and ethanol at room temperature, distinct spectral absorption lines for water and ethanol can be observed at around 2.46 THz. The interaction of water polar molecules is discussed based on the THz spectra of water vapor with different humidity levels at atmospheric pressure. Furthermore, THz spectra of water were obtained in a vapor-liquid coexistence at a pressure of 14.6 kPa, in which an absorption peak at 2.585 THz appeared just after the gas cell was evacuated. This peak may be due to clusters of water molecules.
