Introduction

Condyloma acuminate is a painless growth over the skin surface, which is usually, associated with human papillomavirus (HPV) types 6 and 11 [1]. Buschke-Löwenstein tumor (BLT) or giant condyloma acuminatum (GCA) is a progressively growing, cauliflower-like, locally destructive tumor that is considered to be a verrucous carcinoma, which is an intermediate state between condyloma and squamous cell carcinoma [1,2]. Patients who suffer from these tumors are susceptible to secondary infections, foul odor and fistulations. These tumors can grow rapidly and be potentially fatal to immunocompromised individuals [2, 3]. A wide, radical surgical excision of the mass is considered the primary treatment, while a close follow-up is necessary due to its frequent recurrence and malignant potential [1-3]. In this article we report the case of a 71-year-old man who was misdiagnosed for 20 years with hemorrhoidopathy and was finally treated with wide excision of a giant perianal Buschke-Löwenstein tumor.

Case Report

A 71-year-old male patient presented in our outpatient clinic complaining about a perianal mass accompanied by scarce episodes of rectal bleeding. His symptoms initially began 20 years ago but at the time he was misdiagnosed with hemorrhoidopathy and was treated accordingly. Twelve years ago he suffered from myocardial infarction and was treated with a double percutaneous transluminal coronary angioplasty. In the same year he was diagnosed with abdominal aortic aneurysm and was treated with endovascular repair. Four year ago he was diagnosed with b-cell lymphoma and is under medical treatment until now. Clinical examination of the anorectal region revealed a gigantic tumor, which was a case of GCA of Buschke-Löwenstein (Figure 1). Under general endotracheal anesthesia and in lithotomy position the patient was subjected to wide, radical excision of the mass using electrocautery. The specimen (Figure 3) was sent for histopathological examination. The patient had an uneventful post-operative course and was discharged on the first postoperative day.
Discussion

BLT is a sexually transmitted disease triggered by HPV, more frequently subtypes 6 and 11 [2,4]. Its incidence is 0.1% in the general population with a 2.3:1 male to female ratio [2,5]. It usually manifests clinically as a palpable mass that can be accompanied by pain, fistulas, bleeding and pruritus [4]. In the majority of the cases it starts from long-standing condylomata that can reach up to 10-15 cm. The evolution period usually ranges from 2.8 to 9.6 years [1]. The most important risk factors include anal receptive sex, immunosuppression, HIV infection, chronic irritation and poor personal hygiene [1]. BLT is sometimes associated with severe morbidity due to its invasive growth which can result into local tissue destruction and occlusion of the rectum, especially in cases of malignant transformation into squamous cell carcinoma [6,7]. Histologically BLT has benign appearance with negligible cellular atypia, papillomatosis, koilocytosis and epithelial hyperplasia [1,2]. However, these histological features are very similar to those of verrucous carcinoma and some authors do not differentiate between these diseases [4]. Nonetheless, BLT has low metastatic potential [4]. Because of its scariness and lack of controlled studies, there are no gold standards in managing BLT [2,7]. Therapeutic options include topical agents (podophillin, bleomycin, interferon and 5-fluorouracil), systemic therapy with chemoradiation, cryotherapy with liquid nitrogen, use of carbon laser and surgical management [2,7]. Surgical resection with wide tumor-free surgical margins seems to be the treatment of choice due to BLT’s high rate of recurrence (66%) and malignant transformation (56%) [1]. The effectiveness of adjuvant therapy remains under study [7].

Conclusion

In this article we present a case of a patient who presented with a large anorectal mass that was proven to be a BLT. He was initially misdiagnosed with hemorrhoidopathy twenty years ago. This delay in the correct diagnosis might affect the patient's life quality as it increases the risk of recurrence and malignant transformation.
