Abstract

Illicit usage in athletes of androgenic anabolic steroids, such as testosterone and its derivatives, can cause myocardial dysfunction, that is usually reversible after the end of the abuse. However, in some cases myocardial dysfunction can be severe and irreversible for reasons that are not clear. We report the case of a 31-year-old patient, bodybuilder, who came to our attention for acute heart failure secondary to a dilated cardiomyopathy, with severe and irreversible left ventricular systolic dysfunction (LVEF 23%). Instrumental and laboratory examinations excluded myocarditis and coronary artery disease as a possible etiology of the left ventricular systolic dysfunction. The patient had previously taken different types of androgenic anabolic steroids (testosterone and derivatives), for almost twelve years and also growth hormone (GH) for 1 year, and never stopped hard exercise training throughout in order to improve his performance as a bodybuilder. He had been diagnosed with left ventricular systolic dysfunction, symptomatic for heart failure (NYHA class II-III), about six months after cessation of the abuse and the severe LV dysfunction did not reverse. We believe that the abuse of steroids may be the cause of our patient’s left ventricular dysfunction, that became worse and irreversible due to many years of usage, in association with intense physical training and GH; our hypothesis is strengthened by experimental studies in animals and autopsy immunohistochemical studies demonstrating a direct cardiotoxicity of anabolic androgenic steroids. The possible etiologic mechanism underlying acute and chronic cardiotoxicity in humans of these substances in humans warrants closer clinical investigation.

Introduction

Numerous athletes make use of anabolic-androgenic steroids (AASs), the synthetic derivatives of the male hormone testosterone, to increase and strengthen muscle mass, even if this is illegal but impossible to control. The effect of abuse of these hormones on the body and in particular on the heart is still not entirely known. These substances can produce adverse effects on various organs, and in literature several cases of cardiac disease have been reported in athletes after previous abuse of AASs [1-13] documenting dilated cardiomyopathy (DCM). However only few of them have shown irreversible DCM [1,6,8,13]. We report the case of a 31-year-old white male, bodybuilder, who had previously used AASs. He presented to our attention with dilated cardiomyopathy and severe irreversible left ventricular systolic dysfunction. We focused on the mechanism of AASs induced irreversible LV dysfunction.

Case Report

The patient was a 31-year-old man, bodybuilder, with no family history of cardiac disease and no cardiovascular risk factors. When the patient came to our attention, he had received a diagnosis of dilated cardiomyopathy (undocumented) about one year before and started treatment with beta-blockers and diuretics; he then spontaneously suspended the therapy after a few months. He admitted having previously taken high doses of various AASs to increase his muscle mass, including stanozolol, boldenonum,
trenbolone, testosterone propionate and enanthate. His abuse of these substances had lasted for twelve years, and he also took human growth hormone for 1 year. He had stopped taking these substances one year before he came to our attention, after the diagnosis of dilated cardiomyopathy. The patient presented at the emergency room of our hospital with worsening dyspnea and orthopnea, symptoms that had started two months before and showed an increasing trend. He was apyretic, blood pressure was 120/80 mmHg, the heart rate was 90 bpm, the respiration rate was 25 breaths/min and peripheral arterial oxygen saturation was 95%.

Physical examination showed a muscular man, the apex beat was not evident, the jugular at baseline showed an absent X’ descent with a positive hepato-jugular reflux and heart sounds were regular at the auscultation; there was also minimal ankle swelling and bilateral basal crackling rattles were audible at lung auscultation. The ECG showed a sinus rhythm with a frequency of 88 bpm, signs of left atrial enlargement, a left axial deviation and negative T-waves on D1 and aVL and from V4 to V6; no previous recent ECG was available for comparison. Chest X-ray showed pulmonary edema and an acute bronchopneumonia focus. Transthoracic echocardiography (TTE) revealed a dilated cardiomyopathy with severe left ventricular systolic dysfunction (LVEF 23% calculated with the Simpson biplane method) and dilatation (telediastolic diameter 79 mm) with moderate uniform hypertrophy (Figure 1a & 1b). There was grade II diastolic dysfunction (E/A waves ratio 1,9; E wave deceleration time 144 msec), “B-bump” on M-mode examination at the mitral valve level and an average E/e' at tissue doppler analysis at the upper limit of the “grey zone”: 14 (Figure 2a-2d); global longitudinal peak systolic strain (GLPSS) was -7,4%; the left atrium was dilated; the right ventricle was dilated, slightly hypococontractile (tricuspid annular plane systolic excursion, TAPSE, 16 mm) with a dilated right atrium; the inferior cava vein showed a normal dimension and collapsibility.

Figure 1a: Transthoracic echocardiography in the acute phase showing significant left ventricular dilatation (EDV 269 ml) and systolic dysfunction (LVEF 23% calculated with the Simpson biplane method): apical 4-chamber views in telediastole.

Figure 1b: EDV: end diastolic volume; LVEF: left ventricular ejection fraction.
Figure 2a: Evaluation of left ventricular diastolic function showing grade II diastolic dysfunction in the acute phase: a mitral inflow pattern with E/A waves ratio 1.9.

Figure 2b: Major “B-bump” on M-mode examination at mitral valve level.

Figure 2c: An average E/e’ ratio at TDI analysis at basal septal and lateral level of 14 (grey zone).
Laboratory tests showed increased leucocytes, a mild increase of red blood cells and hematocrit (hemoglobin: 16.7 g/dl, hematocrit: 53.3%), mildly increased systemic inflammatory markers (C-reactive protein: 13.2 mg/l), moderate renal failure (eGFR: 61 mL/min). A peak troponin measurement showed a value of 0.118 ng/ml (our hospital cut-off value is 0.045 ng/mL), NT-proBNP was elevated (1810 pg/mL) and total serum cholesterol was 191 mg/dl, with LDL 142 mg/dl and HDL 14 mg/dl. Virological tests were negative. The patient was promptly treated with intravenous diuretics, antibiotic and therapy for heart failure was also started. After stabilization, the patient underwent cardiac magnetic resonance (CMR) imaging with gadolinium contrast that highlighted a small area of late gadolinium enhancement (LGE) at the inferior basal septum level and ruled out the presence of myocardial edema. It also confirmed significant dilatation and left ventricular systolic dysfunction (LVFE: 18%; telediastolic volume 388 mL indexed 155 mL/m², parietal mass FD 238 gr, telediastolic diameter 56 mm, telesystolic volume 202 mL, indexed /BSA 80 mL/m²), right ventricular systolic dysfunction (RVFE: 22%). Abdominal ultrasound highlighted mild hepatic steatosis with hepatomegaly. Coronary computed tomography ruled out coronary artery disease.

After about 40 days, an echocardiographic evaluation showed no functional improvement. In view of the severe left ventricular systolic dysfunction and of the lack of improvement, we decided to implant a subcutaneous implantable-cardioverter-defibrillator (S-ICD).

**Discussion**

Our case highlights an interesting presentation of a dilated cardiomyopathy with acute decompensated heart failure one year after cessation of anabolic steroids in a patient who had performed intensive physical training, and showed no improvement of the ejection fraction after cessation of the abuse and initiation of conventional heart failure therapy. In literature there are several reports documenting AAS-induced cardiotoxicity and in particular DCM [1-13] (Table 1) although few of them indicate irreversible effects on cardiac muscle performance [1,6,8,13] Table. We believe that what can happen in irreversible myocytes damage like in ours patient or even in fatal cases [14,15], is a more profound damage to the myocytes that can be caused by the synergism of AAS, possibly at high dosage and for a prolonged span of time with other factors that enhance the AAS damage, first of all strenous exercise training. We will examine first the AAS general toxic effect mechanisms on cardiac myocytes and then the AAS synergism with strenous exercise and with other potential myocites damaging factors like the growth hormone (GH).

Regarding the general AAS cardiac toxic effect AASs can have numerous cardiovascular side effects and they have a proven direct cardiotoxicity [16]. The mechanisms underlying this cardiotoxicity are still not properly understood, but some studies suggest that the adverse effects of AASs on cardiac muscle can be direct: in rat cardiomyocytes, AASs induce apoptotic cell death in a dose-dependent manner [17]. The apoptotic process may be triggered by a membrane receptor–second messenger cascades that increase polyamines which are known to mediate uncontrolled transmembrane Ca\(^{++}\) flux and also by increasing intracellular Ca\(^{++}\) via Ca\(^{++}\) influx and Ca\(^{++}\) mobilization from the sarcoplasmatic reticulum [17].

The uncontrolled increase of Ca\(^{++}\) affects apoptotic mitochondrial membrane permeability and triggers the release of apoptogenic factors including caspase-9 from damaged mitochondria [17]. This mechanism was confirmed by an in-vitro study on the cardiomyocytes ultrastructure of rodents after AASs exposure demonstrating mitochondria and myofilibrals aberrations similar to those observed in the early stages of human heart failure [18].

Post-mortem studies have corroborated the apoptotic mechanism. In a post-mortem immunohistochemical study, histological analyses were performed on heart tissue of two bodybuilders: the analysis showed important myocytes and endothelial cells apoptotic alterations [14], after various years of abuse of methandienone and nandrolone; these bodybuilders also had a history of very strenuous training that could have enhanced these histopathological alterations. The clinical consequence of this myocardial damage has been corroborated in numerous clinical studies. In athletes that routinely used AASs, the onset of a subclinical impairment of both systolic and diastolic myocardial function has been reported even several years after the cessation of the abuse [13] Table. A study comparing groups of athletes, users and non-users of AASs, showed significantly lower e'/a' ratios at tissue Doppler imaging (TDI) analysis in users at both the basal interventricular septum and the left ventricular lateral wall (both p<0.01) levels, in comparison with non-users; in addition, at strain rate imaging (SRI) analysis, peak systolic longitudinal left ventricular strain and strain rate were both significantly reduced at the mid interventricular septum and at the left ventricular lateral free wall level in users of AASs compared to non-users.

The severity of these subclinical alterations was directly correlated with the mean dosage [19] and duration of AASs abuse [20]. A recent cross-sectional cohort study compared a group of male weightlifters who had used AASs (86 men) in the last two years with a group (54 men) with no history of abuse: at transthoracic echocardiography AASs users demonstrated a relatively reduced left ventricular systolic function (mean±SD
LVEF = 52±11% vs. 63±8%; P<0.001) and diastolic function (E' = 9.3±2.4 cm/s vs. 11.1±2.0 cm/s; P<0.001). Additionally, AASs users had a greater coronary artery plaque volume than non-users at coronary computed tomography (CCT) analysis [21]. Our patient had a negative coronary computed tomography, probably due to his younger age compared to the patients of this study, despite the altered serum lipids. Regarding the synergistic effect of strenuous exercise with AAS, there are post-mortem autopsy studies that suggest that strenuous exercise combined with AAS destroys the mitochondria by triggering a caspase cascade that brings about cell death via a more intense apoptosis [17].

Then, the loss of cellular energy production causes chronic hypoxia of the cardiac muscle and cell death can ensue due to apoptosis rather than necrosis. In addition, nandrolone could act through blocking or down regulating the mechanism implicated in the improvement in antioxidant defense in animal during exercise as demonstrated in animals [22]. GH is another potential harmful substance when taken at high dosage for long periods of times as our patients did for almost 1 year. Concomitant use of AAS and GH further increased LV mass and associated with concentric remodeling of LV [23].

Although left ventricular contraction is impaired in congenital GH deficiency, long term GH excess leads to cardiac hypertrophy and decreased cardiac function [24]. Our case recalls another literature report of a 41 body-builder with severe and irreversible dilated cardiomyopathy that had taken AAS and GH (actually insulin-like growth factor-1 that is an active metabolite of GH) for like heavy metal contamination of the myocardium (mercury in particular) as previously demonstrated in idiopathic dilated cardiomyopathy [25]. Our patient did not have dental amalgama fillings [26] but ate fish regularly 1-2 times/week so potential mercury exposure was modest. A hair analysis could be of aid for chronic heavy metal toxicity screening [19]. Our patient also presented abnormal plasma lipoproteins and laboratory signs of hepatotoxicity: these are other possible side effects of anabolic steroids abuse [27]. Echocardiography can have an important role in the detection of subclinical systo-diastolic dysfunction in AASs users and can be a useful way to discourage the use of these substances in sportmen, revealing initial forms of heart injury through SRI and TDI analysis [20].

**Conclusion**

Long abuse of AAS along with intense physical exercise and GH conjured up irreversibly damaged cardiac myocytes mainly by activating apoptotic mechanism rather than causing necrosis. The abuse of AAS and GH by athletes to improve their performance needs to be strictly controlled and forbidden in view of the possible onset of serious, potentially irreversible cardiovascular diseases. The cause-effect relationship between AASs abuse and the onset of heart failure and irreversible cardiotoxicity mechanisms warrant closer investigations.
